

Polar Coordinates

Article by Marianne Freiberger

If you have learnt about coordinate geometry at school, then the coordinate system you used was probably the Cartesian one. The Cartesian system describes the location of each point p in the plane by two coordinates (x, y) . To find p you start at the point $(0, 0)$ and walk a distance x parallel to the horizontal axis and a distance y parallel to the vertical axis.

We take Cartesian coordinate system for granted these days, but when it first became popular 17th century (in part due to the mathematician René Descartes after whom it is named) it was nothing short of a revolution. For the first time in history it enabled people to describe geometric shapes by equations. For example, The equation

$$y = 2x + 1$$

describes a straight line, the equation

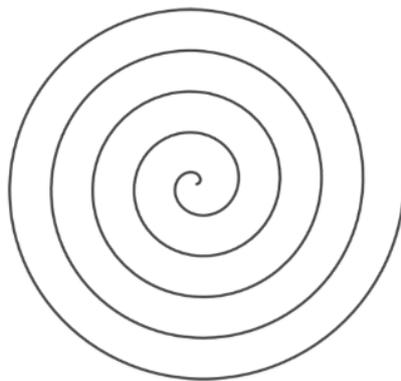

$$y = x^2$$

describes a parabola, and the equation

$$x^2 + y^2 = 4$$

describes a circle.

Can all geometric shapes be described so easily, using comparatively simple equations? Consider the spiral shown in the picture below. It's an example of an Archimedean spiral and is characterised by the fact that the turns of the spiral are evenly spaced.

It's far from obvious how to describe this spiral using Cartesian coordinates. There is a formula that does this, but it is not pretty — you can see it below.

But never fear — something amazing happens when you exchange Cartesian coordinates for polar coordinates. Instead of describing the location of each point p in the plane by an x -coordinate and a y -coordinate, the polar system uses a coordinate called r and a coordinate called θ .

The coordinate r is the distance from $(0, 0)$ to p along a straight radial line, and θ is the angle formed by that radial line and the positive x -axis, measured anti-clockwise from the x -axis to the line.

In polar coordinates the Archimedean spiral above is described by an equation that couldn't be simpler:

$$r = \theta$$

In other words, the spiral consists of all the points whose polar coordinates (r, θ) satisfy this equation.

In general Archimedean spirals are described by equations of the form

$$r = a\theta$$

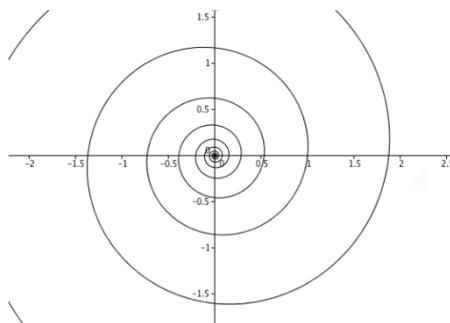

for a a positive real number.

If you prefer a physical interpretation of your geometric shapes, an Archimedean spiral is what you get when you trace the path of a point that moves out from the centre at constant speed along a line that rotates with constant angular velocity.

Another famous family of spirals consists of the logarithmic spirals, whose polar coordinates are given by equations of the form

$$r = ae^{b\theta}$$

Where a and b are positive real numbers and e is the base of the natural logarithm. The picture below shows a logarithmic spiral with $a = 1$ and $b = \frac{1}{5}$.

Logarithmic spirals are famous because they often occur in nature. You can see them in the turns of a snail shell, in many plants and even in the arms of spiral galaxies. The 17th century mathematician Jacob Bernoulli was so fascinated by this beautiful shape, he called it the "spiral mirabilis" (miraculous spiral) and asked for it to be engraved on his tombstone. Unfortunately the engravers got it wrong and he ended up with an Archimedean spiral on his grave instead.

So which coordinate system is best, the polar one or the Cartesian one? It depends on what you are trying to do. Some shapes work better in the Cartesian system and some in the polar system. The important thing is that a change from one system to the other can turn gruesome equations into beautifully simple ones. If in doubt explore both options!

Cartesian equation for the Archimedean spiral

In Cartesian coordinates the Archimedean spiral above is described by the equation

$$y = x \tan \sqrt{(x^2 + y^2)}.$$
